The observed per capita annual expenditure (Rs 131) in our study was only about 1% of the per capita national income (Rs 12 782 in 1997–98).10

Previous studies as well as ours clearly show that there is a greater flow of monetary resources from the community to the private health sector. The per capita government expenditure (central level) on health and family welfare in 1998 was only Rs 33 (according to the Plan budget of 1998), which was much less than the actual per capita expenditure on health (Rs 131). On the other hand, the public health sector faces difficulties in running the facilities without recovery of the cost of services. The mechanisms by which public health services can generate resources could be by levying user fees or indirectly through an insurance system. While generating resources for health is essential, protecting the poor from the high costs of medical care is equally important. These issues need to be debated in India to evolve a consensus.

ABSTRACT

Background. There are very few community-based studies on the prevalence of asthma in Indian children. We aimed to estimate the prevalence of asthma in children under 12 years of age and to study possible differences in the prevalence of childhood asthma in urban and rural areas of Tamil Nadu.

Methods. A total of 584 children from Chennai and 271 children from 25 villages around Chennai formed the urban and rural groups, respectively. From November 1999 to February 2000, data were collected using a simplified version of the ISAAC questionnaire, which was administered by trained students. Symptoms suggestive of asthma or hyperreactive airways disease in children under 12 years of age were recorded from the selected urban and rural populations by questioning the parents. The results were analysed separately for children 0–5 and 6–12 years of age.

Results. Of the 855 children studied, the overall prevalence of breathing difficulty (including asthma) was 18% and the prevalence of ‘diagnosed’ asthma was 5%. Twenty-two per cent of urban and 9% of rural children 6–12 years of age reported breathing difficulty ‘at any time in the past’ (p<0.01). A significantly higher proportion of 6– 12-year-old urban children also reported nocturnal dry cough (28.4% v. 18.7%, p<0.05). Urban children reported recent wheeze more often than rural children (92% v. 77%, p=0.01).

Conclusions. Symptoms suggestive of asthma were present in 18% of children under 12 years of age. Though the prevalence of diagnosed childhood asthma was about 5% in both urban and rural areas, the prevalence of ‘breathing difficulty’ and nocturnal cough was significantly higher among urban children in the age group of 6–12 years. Children living in urban areas also reported ‘recent wheeze’ more often than rural children. Our data suggest that the actual prevalence of asthma and other ‘ wheezy’ illnesses may be higher than that previously documented. Further studies are needed to confirm the difference in prevalence between urban and rural children and also to identify possible causes that could account for the higher urban prevalence of asthma in Tamil Nadu.

INTRODUCTION

Asthma in childhood is a chronic disease and, when severe, often results in increased morbidity for the patient and indirect economic losses for the community. Currently, much attention is being given to the rise in prevalence of childhood asthma worldwide.12 The basis for the increase is not known. A number of studies have examined the various factors involved such as preva-

The prevalence of atopy in a region, allergen exposure, early and recurrent respiratory viral infections in childhood, poverty, diet and obesity, number of siblings in the household, indoor ozone levels, and racial, geographic and socioeconomic differences. Though many of these factors have been associated with an increase in the severity of asthma, the extent to which they contribute to the development of asthma is still not clear.

The recent International Study of Asthma and Allergies in Childhood (ISAAC) and European Community Respiratory Health Survey (ECRHS) have not only produced some information about the prevalence rates of asthma in low-income countries, but also provided a well-validated and easily reproducible method for conducting further studies on the prevalence of asthma. However, there are very few community-based studies on the prevalence of asthma in Indian children and these have given conflicting results. We estimated the prevalence of asthma in children <12 years of age and possible differences in prevalence to asthma between urban and rural areas of Tamil Nadu, south India.

METHODS

The study was conducted in 25 villages in and around the townships of Uthiramooro, Karunguli and Madhuranthakam in Chengalpattu district of Tamil Nadu and 5 low-income urban areas (Periamet, Egmore, Chintadaripet, Pallavan Salai and Koyambedu) of Chennai city. The investigators were well-trained students of the Sociology Department of Madras Christian College, Chennai. A questionnaire based on the one used in the ISAAC study was used with some modifications to make it simpler, retaining only those questions that were related to asthma. The questionnaire had been translated into Tamil and validated at the time the ISAAC survey was conducted in Tamil Nadu a few years ago; the same questionnaire was used.

A door-to-door survey was conducted at a time when all the family members were expected to be at home. Everybody in the community who could be met and interviewed within a timeframe was included. Self-reported answers by parents of children <12 years of age were used to collect the required information. The response rate was 92%. No clinical examination was done to confirm the diagnosis (see Box for the questionnaire).

### Statistical methods

Univariate analysis was carried out separately for each factor (question). The results were analysed using 2-way and 3-way contingency tables for age, sex and residential status. Chi-square tests of significance were carried out to test for differences between proportions. Significance was reported at 5% level. The standardized rates were calculated using direct standardization methods.

### RESULTS

A total of 855 children were studied from November 1999 to February 2000. The distribution of these children according to age, sex and place of residence is given in Table I. There were 584 children from urban and 271 from rural areas and the sex distribution was similar in both the groups.

#### Overall prevalence of respiratory symptoms

Table II shows the overall prevalence of reported symptoms. There was a high prevalence of breathing difficulty and nocturnal dry cough among the children studied. Breathing problems including wheeze at some time in the past were reported by 18% and reported nocturnal dry cough by 21%, though a definite history of asthma was elicited only in 5%. About 18% of children had wheezing episodes during the past 12 months. Exercise-induced wheezing was reported by 7% and a family history of wheezing illness was present in 5% of children.

#### Urban–rural differences

Table III shows the comparison of reported respiratory symptoms between children from urban and rural areas. Among the 0–5-year-old children there was no significant difference in response to any of the questions between the urban and rural areas. However, among 6–12-year-old children, breathing difficulty (22% v. 9%, p<0.01) and nocturnal dry cough (28% v. 19%, p<0.05) were

The questionnaire had been validated and used to study asthma prevalence in many areas of the world. Compared to rural children (92% difference in the severity of asthma, based on frequency of >4 episodes of wheeze in the past 12 months), family history of asthma or reduced physical activity due to asthma were more common in urban children. Table IV shows the responses given by all those who said ‘yes’ to the first question. The age groups have been combined as the numbers were small. These children were asked for a specific history of symptoms indicating the severity of asthma such as wheezing during the past 12 months, frequency of episodes and sleep or speech disturbance due to wheezing. Recent wheeze (within the past 12 months) was more common in urban children compared to rural children (92% vs. 77%, p=0.01). There was no difference in the severity of asthma, based on frequency of >4 episodes of wheeze in 12 months, between urban and rural children. There was also no difference in the occurrence of speech or sleep disturbance due to wheezing in children in both the groups.

### DISCUSSION

We used a simplified questionnaire based on the ISAAC model, which could detect broad differences in respiratory symptoms, particularly symptoms of asthma, in children 0–12 years of age. The questionnaire had been validated and used to study asthma prevalence in many areas of the world.

We found that ‘breathing difficulty associated with whistling sounds in the chest’ occurred in about 18% of children surveyed and almost the same number reported wheezing in the past 12 months. Nocturnal cough, another symptom suggestive of asthma, was also fairly common (21%), further suggesting that this was a true phenomenon. Our data suggest that wheezing-associated illnesses are more common in children in south India than previously thought. A study in Bangalore revealed that the prevalence of asthma in children <18 years increased steadily from 9% in 1979 to 29.5% in 1998. The rise in prevalence correlated with demographic changes in the city such as increase in the number of industries, density of population and number of automobiles.

The current belief, based mainly on the recent questionnaire-based surveys, is that asthma is more common in western Europe, North America and New Zealand compared to countries such as India and China. This conclusion has been drawn from very few studies done in countries such as India. More such studies are required, on a larger scale, to get a clear picture of the current scenario since the large sizes and complexities of countries such as India and China make it difficult to draw conclusions or extrapolate from a few surveys done in just a few cities.

Our study also reveals an increased prevalence of the symptom complex suggestive of asthma in urban children 6–12 years of age, compared to rural children of the same age and socioeconomic status. However, no rural–urban difference was detected in the younger age group. In younger children, lower respiratory tract viral infections are often associated with cough and wheezing. These diminish markedly by the age of 5–6 years and wheezing beyond that age is generally due to asthma. Our findings are corroborated by a few other recent surveys. Paramesh found that among children 6–15 years of age, the prevalence of asthma in urban children was 16.6% while in rural children it was 5.7%. Among urban children, a higher prevalence of asthma was found among children exposed to heavy traffic, thereby acknowledging the presence of outdoor air pollution as a triggering factor.

Other studies done in north India have reported a prevalence of asthma in 11.6% in Delhi (urban) and 1% in rural children in Punjab. Gupta et al. found that respiratory symptoms were reported by 31% of 9–20-year-old children but the observed asthma prevalence was 2.6% for boys and 1.9% for girls in Chandigarh. Hence, there is a wide variation in reported asthma prevalence from different parts of the country, but few studies have investigated rural and urban differences.

Various researchers around the world are investigating causes for the early development of asthma in childhood. One such study by Celenot et al. from Costa Rica showed that sensitization to house dust mites, low parental education and parental history of asthma were associated factors. Stewart et al. attempted to correlate per capita gross national product (GNP) and the prevalence of asthma. They found a positive association between per capita GNP and wheeze in the past 12 months in the 13–14 years age group, but not in the 6–7 years age group. Yemanerohan et al. studied the frequency of wheeze, chronic cough and atopy in children from urban and rural Ethiopia and showed that there is a positive correlation between urbanization and the development of childhood asthma. Similarly, Addo Yobo et al. have studied the prevalence of exercise-induced bronchospasm in urban and rural school-going children from Ghana. They have reported a higher prevalence of exercise-induced bronchospasm in the ‘urban rich’ group as compared to both ‘urban poor’ and ‘rural’ groups. Another study from India that has compared urban–rural differences found a higher prevalence of asthma in urban children.

Urbanization could mean a number of lifestyle changes, such as change in dietary habits, indoor allergen exposure, pollution, crowding, etc. So far, no single factor has been shown to have a strong correlation with the prevalence of asthma. Studies have suggested that exposure to environmental tobacco smoke, a family history of atopy and pets at home are risk factors associated with symptoms of asthma.

In summary, our data suggest that breathing difficulty associated with wheezing is a common symptom, occurring in approximately 1 in 5 children <12 years of age. Our findings suggest that asthma may be more common than previously believed and that symptoms suggestive of asthma are more common among urban...
Detection of day blood filarial antigens by Og4C3 ELISA test using filter paper samples

S. L. HOTI, A. ELANGO, K. RADJAME, J. YUVARAJ, S. P. PANI

ABSTRACT

Background. The launching of the global filariasis elimination programme has necessitated the use of highly sensitive and specific diagnostic tests. The Og4C3 monoclonal antibody-based ELISA test has been found to be highly specific and sensitive for the diagnosis of filariasis using night blood samples. However, it requires a serum sample which poses problems of transport and storage. Collection of blood samples on filter paper will greatly circumvent these problems. Therefore, we evaluated the utility of the Og4C3 assay on filter paper samples collected during daytime.

Methods. Blood samples were collected from 63 microfilariae (mf) carriers during different time periods in a day on filter paper discs as well as venous blood for sera. The mf carriers and chronic (hydrocele n = 20; lymphoedema n = 120) and acute filariasis (adenolymphangitis n = 39) patients were from the endemic areas and the non-endemic normals were from Uthagamandalam district of Tamil Nadu, India. The filarial antigens in the samples were determined using the Og4C3 filarial antigen assay as per the manufacturer’s instructions (ICU Tropic-Bio, Australia). The sensitivity of the assay on sera and filter paper

ACKNOWLEDGEMENTS
We thank Mrs Nalini Manuel from ‘ASHA’ and the team of students from the Sociology Department of Madras Christian College for conducting the survey. We would like to express our gratitude to Mrs Anderson of the Asthma Foundation of India for data entry and secretarial assistance.
